To prospectively characterize serial changes in hepatic MRI signal intensity and hepatic histopathology in a porcine model of selective portal vein embolization. In eight healthy female mini-pigs, serial MRI of the liver was performed before and at 1, 3, 7, 10, and 14 days after portal vein embolization. Histologic analysis of the liver was performed in a separate cohort of five of these animals. After portal vein embolization, a distinctive, although nonuniform, pattern of hepatic enhancement was observed. Changes in signal intensity were most pronounced in the parenchyma of portal branches that fed portal branches that embolized. Although the signal intensity of the parenchyma adjacent to the portal branches embolized decreased over time, it was not substantially reduced by day 14. Histologic changes included early subcapsular edema, hemorrhage, hepatocyte loss, and necrosis. The pattern of MRI enhancement after portal vein embolization was different from that after portal vein ligation, where a uniform hypointensity was observed and where histologic changes were confined to the hepatic sinusoids. The changes in MRI signal intensity after portal vein embolization can
